Cañón*<br>*Laboratorio de Genética, Facultad de Veterinaria, Universidad Complutense de Madrid, Madrid, Spain. ${ }^{\dagger}$ Departamento de Estadística<br>e Investigación Operativa, Facultad de Ciencias, Universidad de Oviedo, Oviedo, Spain

## Summary

The formulae for computing the so-called Sib Index using codominant alleles for (1) fullsib and (2) half-sib parentage are given. Hypothesis testing is based on the distribution of conditional likelihood ratio or Bayes' factor. Thresholds for rejecting the null hypothesis and $P$-values were obtained in function of the number of alleles and their frequency distributions. Simulations showed that a relatively low number of marker systems (e.g. 20) are enough to accept the hypothesis of sib parentage with a reasonable power for usual significance levels, but that a higher number would be necessary if full-sib against half-sib parentage is the contrast to be carried out. The effect of sampling variation on the allele frequencies on power calculations is also analysed.

Keywords Bayes' factor, molecular markers, sib parentage test.

## Introduction

There is a need to check the correct paternity relationships to be used for predicting the genetic merit of the individuals included in the breeding programme through the numerator relationship matrix (Henderson 1976), especially for farmed animal species. It is well known that errors in paternity assignment delay genetic progress, whose magnitude under certain circumstances reaches that of the amount of paternity errors in the pedigree (Ron et al. 1996). While in these farmed species paternity testing is generally concerned with the exclusion of paternity, in others the requirement is to establish family relationships for legal, social or medical reasons (Pena \& Chakraborty 1994). Exclusions of paternity are irrefutable and the power of a set of genetic markers to exclude is systematically computed into the exclusion probability, which depends on allelic frequencies in the population (Jamieson 1994; Jamieson \& Taylor 1997). The availability for most domestic and many

## Address for correspondence

[^0]wild animal species of a large number of highly informative DNA markers and their utility for checking parentage have increased the possibilities (Goodnight \& Queller 1999; Ritland 2000; Fiumera \& Asmussen 2001). In particular, showing whether two individuals are sibs when no parental information is accessible is one of the most frequent questions asked for at animal genetic services or forensic laboratories. It is clear that under the situation, in which exclusion of paternity is the goal, the acceptance of the exclusion is irrefutable because, assuming no mutations and no laboratory errors, a descendent must carry parental alleles. However, proof of sib-ships depends on statistical inference. This paper presents formulae to compute Sib and Half-sib Indexes using codominant markers when parent information is unknown and their distributions under different amounts of marker information.

## The conditional likelihood ratio

The conditional likelihood ratio (LR) or Bayes factor has traditionally been considered as the way to evaluate the evidence in paternity disputes (Aitken 1997). It is the ratio of two probabilities, the probability of $G$ (the genotype of the individuals) when $S$ (both individuals are sib related) is true $[\operatorname{Pr}(G / S)]$ and the probability of $G$ when $\bar{S}$ is false $[\operatorname{Pr}(G / \bar{S})]$. The likelihood ratio takes values between 0 and $\infty$, while its logarithm, which receives the name of the weight of the evidence (Good 1950), takes values on $(-\infty, \infty)$. It has been
argued in favour of the use of the logarithm of the likelihood ratio that the results it produces are in accordance with the weighing of evidence in the scale of justice.

The hypotheses that we wish to test are: (a) S, both individuals are sibs, (b) I, the individuals are unrelated random individuals from the referenced population, (c) HS, both individuals are half-sibs. Individuals are genotyped and the result is G. Large LR values argue in favour of sib-ships, whereas small values argue against it.

In the context of this paper the probability ratio is called Sib Index or Half-sib Index.

## Calculation of the Sib Index for full-sib testing

Formally, our interest is to calculate the joint probability of two genotypes conditioned to the fact that the individuals carrying them are sibs, and compare it with the probability of those genotypes when the individuals are not sibs. In order to do that, and assuming that we are dealing with several loci, we will show first how to do it with a particular locus.

For a given locus $A$, let $A_{i} A_{j}$ and $A_{k} A_{l}$ be the genotypes for $A$ of the two individuals, and denote by $s$ the event of them being indeed whole sibs.

We can define the Sib Index for locus $A$ as

$$
S I_{A}=\frac{P\left\lfloor A_{i} A_{j} \wedge A_{k} A_{l} \mid s\right\rfloor}{P\left[A_{i} A_{j} \wedge A_{k} A_{l} \mid \neg s\right]} .
$$

The probability in the denominator equals, under HardyWeinberg equilibrium $\left(2-\delta_{i j}\right)\left(2-\delta_{k l}\right) p_{i} p_{j} p_{k} p_{l}$, where $p_{m}$ stands for the frequency of allele $m$ in the population, $m=1, \ldots, n, n$ being the number of alleles in locus $A$, and $\delta_{m n}$ is the well-known Kronecker Delta, which equals 1 if $m=n$ and 0 otherwise. This result is obvious because both individuals are independent in this situation.

To obtain the probability in the numerator, we need a little algebra. We know that $P\left[A_{i} A_{j} \wedge A_{k} A_{l} \mid s\right]=$ $P\left[A_{k} A_{l} \mid s \wedge A_{i} A_{j}\right] P\left[A_{i} A_{j} \mid s\right]$. Now, $s$ gives no information for the calculus of $P\left[A_{i} A_{j}\right]$, hence $P\left[A_{i} A_{j} \mid s\right]=\left(2-\delta_{i j}\right) p_{i} p_{j}-$ remember we are assuming HW equilibrium.

We are therefore interested in obtaining the probability of the genotype of one sib conditioned to the fact that it is indeed a sib of the other and to the genotype of the latter. Now,
$P\left[A_{k} A_{l} \mid s \wedge A_{i} A_{j}\right]=\sum_{\alpha, \beta, \gamma, \delta=1}^{n} P\left[A_{k} A_{l} \wedge G P=\left(A_{\alpha} A_{\beta} \times A_{\gamma} A_{\delta}\right) \mid s \wedge A_{i} A_{j}\right]$, where GP is the genotype of a hypothetical parental mating. But

$$
\begin{array}{rl}
\sum_{\alpha, \beta, \gamma, \delta=1}^{n} & P\left[A_{k} A_{l} \wedge G P=\left(A_{\alpha} A_{\beta} \times A_{\gamma} A_{\delta}\right) \mid s \wedge A_{i} A_{j}\right] \\
= & \sum_{\alpha, \beta, \gamma, \delta=1}^{n} P\left[A_{k} A_{l} \mid G P=\left(A_{\alpha} A_{\beta} \times A_{\gamma} A_{\delta}\right) \wedge s \wedge A_{i} A_{j}\right] \\
& P\left[G P=\left(A_{\alpha} A_{\beta} \times A_{\gamma} A_{\delta}\right) \mid s \wedge A_{i} A_{j}\right]
\end{array}
$$

The sum is taken through all the possible matings for a locus with $n$ alleles, but, as $P\left\lfloor G P=\left(A_{\alpha} A_{\beta} \times A_{\gamma} A_{\delta}\right) \mid s\right.$ $\left.\wedge A_{i} A_{j}\right\rfloor \neq 0$ only for those matings in which one parent carries at least one $A_{i}$ allele and the other carries at least one $A_{j}$ allele, it reduces to

$$
\begin{aligned}
\sum_{\alpha, \beta=1}^{n} P\left[A_{k} A_{l} \mid G P\right. & \left.=\left(A_{i} A_{\alpha} \times A_{\beta} A_{j}\right) \wedge s \wedge A_{i} A_{j}\right] \\
P[G P & \left.=\left(A_{i} A_{\alpha} \times A_{\beta} A_{j}\right) \mid s \wedge A_{i} A_{j}\right]
\end{aligned}
$$

Now, once the alleles $A_{i}$ and $A_{j}$ are fixed in the genotypes of the parents, the only stochastic variation is due to $A_{\alpha}$ and $A_{\beta}$, so

$$
P\left\lfloor G P=\left(A_{i} A_{\alpha} \times A_{\beta} A_{j}\right) \mid s \wedge A_{i} A_{j}\right\rfloor=p_{\alpha} p_{\beta},
$$

and therefore

$$
\begin{aligned}
& P\left[A_{k} A_{l} \mid s \wedge A_{i} A_{j}\right] \\
& \quad=\sum_{\alpha, \beta=1}^{n} p_{\alpha} p_{\beta} P\left[A_{k} A_{l} \mid G P=\left(A_{i} A_{\alpha} \times A_{\beta} A_{j}\right) \wedge s \wedge A_{i} A_{j}\right] .
\end{aligned}
$$

For example, consider a locus $A$ with three alleles $A_{1}, A_{2}$ and $A_{3}$, and suppose that the reference individual is $A_{1} A_{2}$, his putative sib $A_{1} A_{3}$ and the alleles have frequencies of $p_{1}$, $p_{2}$ and $p_{3}$. Then the possible matings to originate an $A_{1} A_{2}$ individual are

$$
\begin{array}{|l|}
\hline A_{1} A_{1} \\
A_{1} A_{2} \\
A_{1} A_{3} \\
\hline
\end{array} \times \begin{array}{|l|}
A_{1} A_{2} \\
A_{2} A_{2} \\
A_{3} A_{2} \\
\hline
\end{array}
$$

and thus

$$
\begin{aligned}
P\left[A_{1} A_{3} \mid s \wedge A_{1} A_{2}\right]= & 0.5 p_{1} p_{3}+0.25 p_{3} p_{2}+0.25 p_{3}^{2} \\
& +0.25 p_{1} p_{3} \\
= & 0.5 p_{1} p_{3}+0.25 p_{3}\left(p_{1}+p_{2}+p_{3}\right) \\
= & 0.5 p_{1} p_{3}+0.25 p_{3}
\end{aligned}
$$

It can be easily shown that, in general,

$$
\begin{aligned}
P\left(A_{k} A_{l} \mid s \wedge A_{i} A_{j}\right)= & 0.25\left(\left(2-\delta_{k l}\right) p_{k} p_{l}+\delta_{i k}\left(1+\delta_{i j}\right) p_{l}\right. \\
& \left.+\delta_{j l}\left(1-\delta_{i j}\right) p_{k}+\delta_{i k} \delta_{j l}\right)
\end{aligned}
$$

$\forall i, j, k, l \in\{1, \ldots, n\}, n$ being the number of alleles in the locus.

This formula was obtained by trying to provide a unique expression for the explicit, separate formulae deduced for

Table 1 The nine possible cases for $P\left(A_{k} A_{l} \mid s \wedge A_{i} A_{j}\right)$. In rows the possibilities for the individual in the condition; in columns the possibilities for the individual whose genotype's probability is calculated.

|  | Homozygous <br> sharing two <br> alleles $\left(A_{i} A_{i}\right)$ | Homozygous <br> sharing one <br> allele $\left(A_{i} A_{i}\right)$ | Homozygous <br> sharing zero <br> alleles $\left(A_{k} A_{k}\right)$ | Heterozygous <br> sharing two <br> alleles $\left(A_{i} A_{j}\right)$ | Heterozygous <br> sharing one <br> allele $\left(A_{i} A_{l}\right)$ | Heterozygous <br> sharing zero <br> alleles $\left(A_{k} A_{l}\right)$ |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Homozygous $\left(A_{i} A_{i}\right)$ <br> Heterozygous $\left(A_{i} A_{j}\right)$ | $0.25\left(1+p_{i}\right)^{2}$ |  | $0.25 p_{k}^{2}$ |  | $0.5\left(p_{i} p_{l}+p_{l}\right)$ |  |

each sibs' genotype combination, depicted in Table 1, for computer programming purposes. It is important to note that, in case of being implemented in a programme, the genotypes to be the input in the formula have to be stored in the right way, as denoted in Table 1. For example, to compute, $P\left(A_{j} A_{i} \mid S \wedge A_{i} A_{j}\right)$, the haplotype $A_{j} A_{i}$ has to be input as $A_{i} A_{j}$. Otherwise the formula will not work properly. Of course it is possible to generalize a step beyond, but the expression thereby obtained is far more obtuse.
Note that, as expected, the sum of the probabilities along the rows equals 1 .
The Sib Index for locus $A$ would thus be

$$
S I_{A}=\frac{\left(2-\delta_{k l}\right) p_{k} p_{l}+\delta_{i k}\left(1+\delta_{i j}\right) p_{l}+\delta_{j l}\left(1-\delta_{i j}\right) p_{k}+\delta_{i k} \delta_{j l}}{4\left(2-\delta_{k l}\right) p_{k} p_{l}} .
$$

When considering multiple independent loci, as usually happens in the situations in which this procedures are useful, the joint Sib Index would be the product of the different indexes. Hence, $S I=\prod_{m=1}^{M} S I_{m}$.

Figure 1 Empirical probability density functions of the log-Sib Index (up) and log-Half-sib Index (down) under the two hypotheses tested in each (null hypothesis on left). In the middle, empirical pdf of the LogPR of being full sibs $\left(H_{0}\right)$ vs. being half-sibs. All of them obtained for a random set of frequencies for 20 markers with five alleles each and $10^{6}$ simulations.

Note that although this rationale is based on the calculation of a conditional probability on the genotype of one of the putative sibs in order to obtain the joint probability of the two putative sibs' genotype, the choice of the genotype upon which the probability is to be conditioned has no influence on the final result.

## Calculation of the Sib Index for half-sib testing

Although with some variations that we will discuss later on, the situation is fairly analogous to the full-sib case. Assuming the same locus notation as in the previous section, we look for the value of the quotient $\frac{P\left[A_{i} A_{j} \wedge A_{k} A_{i} \mid h s\right]}{P\left[A_{i} A_{i} \wedge A_{k} A_{l} \mid h s s\right]}$, which will be called the Half-sib Index for locus $A$, and denoted as $H S I_{A}$, and where $h s$ denotes the event of the two individuals being halfsibs. For the same reasons as above, we can restrict ourselves to calculate $p\left\lfloor A_{k} A_{l} \mid h s \wedge A_{i} A_{j}\right\rfloor$. Now, instead of expanding this probability by intersecting with the genotypes of the parents, we will do it only with the genotype of the father, denoted as GF, because both individuals share the same father, but not necessarily the same mother. Therefore,

$$
P\left[A_{k} A_{l} \mid h s \wedge A_{i} A_{j}\right]=\sum_{\alpha, \beta=1}^{n} P\left[A_{k} A_{l} \wedge G F=A_{\alpha} A_{\beta} \mid h s \wedge A_{i} A_{j}\right]
$$

Now,

$$
\begin{aligned}
& \sum_{\substack{\alpha=1 \\
\beta \geq \alpha}}^{n} P\left[A_{k} A_{l} \wedge G F=A_{\alpha} A_{\beta} \mid h s \wedge A_{i} A_{j}\right] \\
& =\sum_{\substack{\alpha=1 \\
\beta \geq \alpha}}^{n} P\left[A_{k} A_{l} \mid G F=A_{\alpha} A_{\beta} \wedge h s \wedge A_{i} A_{j}\right] P\left[G F=A_{\alpha} A_{\beta} \mid h s \wedge A_{i} A_{j}\right] \\
& =\sum_{\alpha=1}^{n}\left[P\left[A_{k} A_{l} \mid G F=A_{i} A_{\alpha} \wedge h s \wedge A_{i} A_{j}\right] P\left[G F=A_{j} A_{\alpha} \mid h s \wedge A_{i} A_{j}\right]\right. \\
& \quad+\left(1-\delta_{i j}\right) P\left\lfloor A_{k} A_{l} \mid G F=A_{j} A_{\alpha} \wedge h s \wedge A_{i} A_{j}\right\rfloor \\
& \quad P\left\lfloor G F=A_{j} A_{\alpha} \mid h s \wedge A_{i} A_{j} ل\right. \\
& =\sum_{\alpha=1}^{n} 0.5\left(1+\delta_{i j}\right) p_{\alpha}\left[P\left[A_{k} A_{l} \mid G F=A_{i} A_{\alpha} \wedge h s \wedge A_{i} A_{j}\right]\right. \\
& \quad+\left(1-\delta_{i j}\right) P\left\lfloor A_{k} A_{l} \mid G F=A_{j} A_{\alpha} \wedge h s \wedge A_{i} A_{j} . ل\right.
\end{aligned}
$$

Consider the simplest example, in which one individual bears genotype $A_{1} A_{2}$, and the other $A_{3} A_{4}$, all the alleles
being different from each other, we try to find the probability of genotype $A_{3} A_{4}$ conditioned to the fact that a half-sib of him carries $A_{1} A_{2}$. Then

$$
\begin{aligned}
& P\left[A_{3} A_{4} \mid h s \wedge A_{1} A_{2}\right] \\
& \quad=0.5 p_{3}\left[P\left[A_{3} A_{4} \mid G F=A_{1} A_{3}\right]+P\left[A_{3} A_{4} \mid G F=A_{2} A_{3}\right]\right] \\
& \quad+0.5 p_{4}\left[P\left[A_{3} A_{4} \mid G F=A_{1} A_{4}\right]+P\left[A_{3} A_{4} \mid G F=A_{2} A_{4}\right]\right]
\end{aligned}
$$

Now, $P\left[A_{3} A_{4} \mid G F=A_{1} A_{3}\right]$ is the probability of the individual carrying allele $A_{4}$ and the father passing $A_{3}$, which equals $1 / 2 p_{4}$. Therefore, $P\left[A_{3} A_{4} \mid h s \wedge A_{1} A_{2}\right]=0.5 p_{3}[1 /$ $\left.2 p_{4}+1 / 2 p_{4}\right]+1 / 2 p_{4}\left[1 / 2 p_{3}+1 / 2 p_{3}\right]=p_{3} p_{4}$.

As in the previous situation, we can build up a table with all the possible cases, such as Table 2.

As before, it is easy to show that the probabilities in each row sum one, as expected from a well defined probability measure.

Again, a more general formula can be induced from the table:

$$
\begin{aligned}
P\left(A_{k} A_{l} \mid h s \wedge A_{i} A_{j}\right)= & 0.25\left(2\left(2-\delta_{k l}\right) p_{k} p_{l}+\delta_{i k}\left(1+\delta_{i j}\right) p_{l}\right. \\
& \left.+\delta_{j l}\left(1-\delta_{i j}\right) p_{k}\right),
\end{aligned}
$$

and the same comments of the previous case regarding alleles ordering in the haplotypes apply here.

Thus, the Half-sib Index for locus $A$ is defined as

$$
H S I_{A}=\frac{2\left(2-\delta_{k l}\right) p_{k} p_{l}+\delta_{i k}\left(1+\delta_{i j}\right) p_{l}+\delta_{j l}\left(1-\delta_{i j}\right) p_{k}}{4\left(2-\delta_{k l}\right) p_{k} p_{l}}
$$

and the joint Half-sib Index for multiple and independent loci is

$$
H S I=\prod_{m=1}^{M} H S I_{m}
$$

## Hypothesis testing

Simulation routines were developed to study the performance of the test under several situations. Empirical power values and probability density functions were obtained for different marker configurations, allele frequency situations and significance levels. Allele frequencies were simulated for populations with 10, 20 and 30 markers, all of them having the same number of alleles, either 5 or 10 . The sets of frequencies were generated in three different ways: at random,
uniformly with slight variations and uniformly with slight variations except but some extreme frequency alleles. Uniform with slight variations means here that if the number of alleles for a certain locus is $n$, each allele is present not with frequency $1 / n$, but $1 / n \pm 0.01 \quad\left(f_{1}=1 / n+0.01, f_{2}=\right.$ $1 / n-0.01$, and so on, with $f_{n}=1 / n-0.01$ if $n$ is even and $f_{n}=1 / n$ if $n$ is odd). Uniform with slight variations but with some extreme frequency alleles means the same as above except that $20 \%$ of the loci involved are considered to have extreme frequency alleles, that is, all the alleles but one are present with frequency 0.01 . The power was obtained for three significance levels: $0.001,0.0001$ and 0.00001 . To obtain the power of one test for a set of allele frequencies, 100000 pairs of individuals were simulated with those frequencies under null and another 100000 under alternate hypotheses. Formulae in Table 1 or 2, depending on the contrast, were applied to the 100000 pairs on each hypothesis, and thus 200000 values of the statistic were obtained, 100000 under each hypothesis. For a significance level $\alpha$, the $(1-\alpha) \times 100$ 000th highest value of the $100000 H_{0}$ values was taken as the rejection threshold, and so the power was obtained as the proportion of $H_{1}$ values above that threshold. Probability density values were empirically approximated by taking histogram values as pdf values, with histogram values calculated for 1000 narrow intervals. The method was applied as well in a real IrishSetter dog breed population, to test the parentage of two putative full sibs. Allelic frequencies were estimated from a total of 64 individuals.

Tables 3-5 show the figures for the different scenarios. As expected, the increase of information from markers results in an increase in power. Reasonable values are obtained for full-sib parentage determination for a nonrare situation of 20 markers with five alleles each. If the number of markers grows up to 30 , maintaining the plausible value of five alleles per marker locus, it makes the test show good levels of power, even for a significance level as low as $10^{-4}$. Raising the number of alleles per locus would keep the power high even for $\alpha=10^{-5}$. As depicted in Fig. 2, in the perhaps overly optimistic situation of having 10 alleles per locus for a total of 30 markers, the density functions of the natural logarithm of

Figure 2 Empirical probability density functions of the log-Sib Index for extreme marker situations: the least informative (10 markers, five alleles/ marker) in the left column and the most ( 30 markers, 10 alleles/marker) in the right. Pdfs were obtained for random sets of allelic frequencies (upper row) and pseudo-uniform ones (lower row).
the test under the null (independent individuals) and alternate (full-sibs) hypotheses have almost no intersection, which makes the contrast have very little error. Results also suggest that the test performs better for uniform allelic frequency distributions than for the cases in which alleles with extreme frequencies are involved.

On the other hand, power values for half-sib testage, both vs. independency and vs. full-sibship are not very encouraging, because for optimum conditions of having 30 markers with 10 alleles each and the lowest significance level, power gets to about $75 \%$ in the best cases. This outcome was expected, as testing for half-sibship with no parent information implies allowing for different genotypes on the non-shared parent, so there is a loss of information which lowers the power of the test. Figure 2 shows this situation more graphically, because distributions under null and alternate hypothesis share much of their support. In any case, for individual purposes, testing is always advisable, as it may happen that the individuals
are in fact genetically distant and $P$-values result conclusive.

Figure 3 shows the plots for a real data set from an IrishSetter dog breed population. A total of 18 molecular markers (microsatellites) were analysed, with the number of alleles ranging from 3 to 14 , the mean number being 6.94 and a mean expected heterozygosity value of 0.64 . Table 6 shows the figures for power in this situation. Reasonable power is obtained only for full-sibship vs. independency comparisons for $\alpha=0.001$.

Simulations were also performed to determine whether sampling variation on the allele frequencies affect power calculations. First, 1000 sets of random allele frequencies for 15 markers, each of them with seven alleles, were generated, and for each set, the power for the independent vs. full sibs test was calculated. The mean power among the 1000 sets was of $0.864 \pm 0.010$ for $\alpha=0.001$. This shows that very different sets of allele frequencies provide similar power estimates, so the power of the test relies in the

Figure 3 Same as Figure 1 for real data from an Irish Setter dog breed population.

Table 6 Power values for real Setter dog breed population data.

|  | $\alpha=10^{-3}$ | $\alpha=10^{-4}$ | $\alpha=10^{-5}$ |
| :--- | :--- | :--- | :--- |
| Independent vs. full-sibs | 0.8155 | 0.6269 | 0.4532 |
| Independent vs. half-sibs | 0.1879 | 0.0707 | 0.0233 |
| Full sibs vs. half-sibs | 0.1167 | 0.0290 | 0.0069 |

number of markers and alleles, more than in the frequencies distribution. For the Irish-Setter population, the estimated frequencies were taken as true values and from them 1000 samples of 25,50 and 100 individuals, respectively, were generated. For each sample of individuals allelic frequencies were re-estimated, and the new estimations were used to calculate the power of the independent vs. full sibs test. The mean power for $\alpha=0.001$ was of $0.775 \pm 0.017$ for a 25 -individual sampling scheme, $0.796 \pm 0.014$ for a 50 -individual one and $0.806 \pm 0.012$ for the 100 samples. We see then that multiplying by four the sample size to estimate the allelic frequencies increases the accuracy of power estimation by only $0.5 \%$, which supports our previous conclusion. We can also conclude that, as expected, the higher the sample size, the more accurate the estimation in terms of deviation with respect to the assumed real value of 0.816 (see Table 6). Nevertheless, with a reasonably low sample size of 50 individuals the mean error in the power estimation is only $2.5 \%$.

Other authors have developed similar methods. Goodnight \& Queller (1999) presented Kinship, a software for performing likelihood tests of pedigree relationships. Their method, however, is based on inaccurate probability calculations. Take, for instance, the most unquestionably wrong case,
that of two supposed unrelated individuals carrying four different alleles for a certain marker, say $A_{1} A_{2}$ and $A_{3} A_{4}$. It is clear that the likelihood of the two genotypes under the nonrelationship hypothesis must be $2 p_{1} p_{2} \times 2 p_{3} p_{4}=4 p_{1} p_{2} p_{3} p_{4}$, where $p_{i}$ stands for the frequency of $A_{i}, i=1, \ldots, 4$. According to Goodnight and Queller's procedure and the formulae in Table 2 of Goodnight \& Queller (1999), the likelihood would equal $\frac{4}{4} p_{1} p_{2} p_{3} p_{4}=p_{1} p_{2} p_{3} p_{4}$, which is clearly incorrect. Probably the inaccuracy lies in the allele by allele approach that they followed in the deduction of their formulae. In any case, their results are not comparable with ours, because they calculate the number of loci needed for a power of 0.5 and a significance level of 0.05 , which is too high a figure for the usual forensic applications. Furthermore, they consider loci with 20 equally frequent alleles per locus, which is a certainly unrealistic situation to simulate.

## Conclusions

Formulae are given to compute the probabilities ratio for different hypotheses when sibs or half-sibs are implied and parents are not known. Results, obtained under the HardyWeinberg assumptions and assuming that population allele frequencies are known without error, show that the amount of information generally used by the service laboratories can be sufficient to test full-sib or, with some less certainty, halfsib parentage, as more marker information will be required to reach equivalent power.
